TECHNICAL NOTE NO. 1217

SPARK-TIMING CONTROL BASED ON CORRELATION OF  
MAXIMUM-ECONOMY SPARK TIMING, FLAME-FRONT  
TRAVEL, AND CYLINDER PRESSURE RISE

By Harvey A. Cook, Orville H. Heinicke  
and William H. Haynie

## SUMMARY

An investigation was conducted on a full-scale air-cooled cylinder in order to establish an effective means of maintaining maximum-economy spark timing with varying engine operating conditions. Variable fuel-air ratio runs were conducted in which relations were determined between the spark timing and the basic factors in engine operation, flame-front travel, and cylinder pressure rise.

Data obtained in this investigation showed that maximum-economy spark timing occurred when the crank angle of maximum rate of pressure rise was  $3^{\circ}$  A.T.C. and that the crank angle of maximum rate of pressure rise and the travel of the flame front were directly related. For fuel-air ratios between 0.06 and 0.10 the highest rate of flame travel occurred when the crank angle of maximum rate of pressure rise was  $3^{\circ}$  A.T.C. The previously mentioned relations are significant in fuel or engine investigations in which engine operating variables affect the spark timing for maximum fuel economy.

An instrument for controlling spark timing was developed that automatically maintained maximum-economy spark timing with varying engine operating conditions. The instrument also indicated the occurrence of preignition.

## INTRODUCTION

The main factors that are considered in the selection of the spark timing for an engine are fuel economy and knock-limited performance. The maximum fuel-economy spark timing becomes relatively more significant when the knock-limited performance of the fuel is increased. Engines with a fixed spark timing are often operated under conditions where a more advanced spark timing would give a

considerable improvement in fuel economy. For this reason means of varying the spark timing are sometimes used but even then the selection of the best spark timing with varying engine operating conditions is a problem.

In this investigation conducted at the NACA Cleveland laboratory, relations between the spark timing and basic factors in engine operation (flame-front travel and cylinder pressure rise) were determined in order to establish an effective means of maintaining maximum-economy spark timing with varying engine operating conditions.

The application of the findings in this investigation afford a convenient means of automatically maintaining maximum-economy spark timing with varying engine operating conditions. An automatic spark-timing-control instrument is described in the appendix.

#### APPARATUS AND PROCEDURE

A full-scale air-cooled cylinder was used in the CUE setup described in reference 1. The crank angle of maximum rate of pressure rise  $\theta_r$  was measured on a diagram of time and rate of pressure change produced on an oscilloscope by the signal from a magnetostriction knock pickup in the cylinder head. Timing marks were produced on the oscilloscope by means of electrical impulses generated in a pair of coils mounted on a carriage near the flywheel. The coils had a common magnetic circuit comprised of soft iron cores, a permanent magnet, and an air gap. Steel lugs projecting from the periphery of the flywheel passed through the air gap. The carriage for mounting the coils traveled on a segment of circular track, which was concentric with the flywheel. A pointer on the carriage indicated the angular position of the coils relative to engine top dead center. Measurement of  $\theta_r$  consisted in moving the carriage until a timing mark coincided with the peak on the oscilloscope diagram, which indicated the maximum rate of pressure rise.

A spark-control instrument described in the appendix was used. The spark timing was manually controlled in runs where  $\theta_r$  was held constant. Automatic control of spark timing was used in runs where the crank angle of passage of the flame front past an ionization gap was held constant.

The ionization gap consisted of a spark plug that was modified by extending the electrodes to form a gap 0.025 inch wide about five-eighths inch inside the combustion chamber. When the ionization gap was used, the knock pickup was removed from the cylinder head and

the modified spark plug was mounted in its place. The hole for mounting the knock pickup and the ionization gap was located in front of the cylinder midway between the front spark plug and the intake valve.

The ignition system for the engine was so connected that the magnetos for the front and rear spark plugs operated on one set of primary-circuit contact points. Therefore, the spark timing for the front and rear spark plugs was the same.

A series of variable fuel-air ratio, constant air-flow runs was conducted with the spark timing manually adjusted to maintain  $\theta_r$  constant at  $3^\circ$  B.T.C.,  $3^\circ$  A.T.C.,  $11^\circ$  A.T.C., and  $15^\circ$  A.T.C. A second series of variable fuel-air ratio, constant air-flow runs was conducted with the spark-timing-control instrument set to maintain constant the crank angle at which the flame front passed the ionization gap. In the second series of runs, the instrument was set to give the same spark timings at a fuel-air ratio of 0.085 as were found in the first series of runs.

## RESULTS AND DISCUSSION

Data obtained with spark timing manually controlled to maintain various crank angles of maximum rate of pressure rise are shown in figure 1(a). Data obtained with automatically controlled spark timing to give constant crank angle of passage of the flame front by the ionization gap are shown in figure 1(b). The curves of figures 1(a) and 1(b) are the same. The matching of the data obtained in the two series of runs shows that  $\theta_r$  is constant when the crank angle of passage of the flame front by the ionization gap is constant. This result shows that a direct relation exists between  $\theta_r$  and flame-front travel.

The relation of indicated specific fuel consumption to  $\theta_r$  for various fuel-air ratios are shown in figure 2. (Data were extrapolated to include a fuel-air ratio of 0.04.) Lines of constant spark timing are also shown. Obviously spark timing must be advanced to achieve the low indicated specific fuel consumptions that are possible with very lean mixtures. The data show that, for any fuel-air ratio, maximum-economy spark timing occurs when  $\theta_r$  is  $3^\circ$  A.T.C. Because the spark-timing-control instrument can maintain  $\theta_r$  constant at  $3^\circ$  A.T.C., the instrument can be used to maintain automatically maximum-economy spark timing when engine operating conditions are varied. This automatic control of spark timing can be used to advantage in conducting fuel or engine investigations.

Two engine operating variables that have a great effect on spark timing for maximum fuel economy are (1) the degree of dilution of the incoming charge by residual gases and (2) the use of internal coolants such as water. These variables were not included in this investigation; however, data (reference 2) in which the relation of exhaust pressure to inlet-air pressure was varied and unpublished data from investigations with various water-fuel ratios show that the relation of maximum-economy spark timing to  $\theta_r$  of  $3^\circ$  A.T.C. is unaffected by these two variables. Other data (reference 2) show that engine speed, compression ratio, and inlet-air temperature do not affect the relation. Even when operating with only one spark plug firing the same relation existed.

The percentage increase in fuel consumption when using constant spark timing or constant  $\theta_r$  compared to operation at maximum-economy spark timing ( $\theta_r = 3^\circ$  A.T.C.) are shown in figure 3. Constant spark-timing data show large variations in percentage increase in fuel consumption over the minimum obtainable at each fuel-air ratio. Operation at constant  $\theta_r$  results in an almost constant percentage increase. For example, during operation with a  $\theta_r$  of  $11^\circ$  A.T.C., the average percentage increase in fuel consumption was about 2 percent (varies from 1.4 to 2.4 percent) over the range of fuel-air ratios.

The spark-timing lines in figure 2 show that the time interval measured in degrees of crankshaft rotation between the spark timing and  $\theta_r$  varied considerably. This variation in time (fig. 4) indicates changes in rate of flame-front travel or rate of combustion because there is a direct relation between  $\theta_r$  and flame-front location.

For each fuel-air ratio a spark timing exists that gives the maximum rate of combustion as indicated by the minimum time from spark timing to  $\theta_r$ . The coincidence of this spark timing for maximum rate of combustion with the maximum-economy spark timing ( $\theta_r = 3^\circ$  A.T.C.) for most of the range of fuel-air ratios (0.06 to 0.10) is significant. The combined effect of maximum rate of combustion and proper timing of pressure rise appears to give maximum fuel economy. These results are consistent with theory in that maximum power should result with constant volume burning at top dead center.

The advance of the maximum-economy spark timing for lean mixtures (below 0.06) beyond the spark timing for minimum time from spark to  $\theta_r$  is probably due to slow burning during initial stages of combustion caused by the low degree of compression of the charge.

## APPLICATION OF RESULTS TO MULTICYLINDER-ENGINE OPERATION

The methods for automatically controlling the spark timing to maintain constant  $\theta_r$  as described for a single-cylinder engine can be applied to multicylinder engines. Magnetostriction knock pickups in the cylinder heads of a multicylinder engine, for example, could be used not only to indicate when knock occurs but also to trigger an instrument for automatically controlling  $\theta_r$ . Then maximum-economy spark timing could be automatically maintained when the fuel-air ratio or other engine operating conditions are varied. In addition, the same instrumentation could actuate a warning signal to indicate the occurrence of preignition.

## CONCLUSIONS

The following conclusions can be made from the experimental data obtained on a full-scale air-cooled cylinder in the investigation of the relations between maximum-economy spark timing, flame-front travel, and cylinder pressure rise.

1. Maximum-economy spark timing occurred when the crank angle of maximum rate of pressure rise was  $3^\circ$  A.T.C.
2. Maximum rate of pressure rise and the travel of the flame front were directly related.
3. For fuel-air ratios between 0.06 and 0.10, the highest rate of flame travel occurred when the crank angle of maximum rate of pressure rise was  $3^\circ$  A.T.C.

4. An instrument for controlling spark timing was developed that automatically maintained maximum-economy spark timing with varying engine operating conditions and indicated the occurrence of preignition.

## APPENDIX - DESCRIPTION OF SPARK-TIMING-CONTROL INSTRUMENT

The automatic spark-timing control (fig. 5) consists of two parts: the control unit, which contains the trigger circuit and amplifier, and the servo unit, which contains the magneto-breaker plate driven by a motor, a position transmitter, and limit switches.

The breaker plate is removed from the magneto and mounted on a shaft, which is aligned with the magneto camshaft but is not coupled to it. The shaft on which the breaker plate is mounted is driven by a two-phase induction motor through a worm gear and wheel with a reduction ratio of 100:1. The position transmitter is driven directly from the motor shaft through a spur gear with an over-all reduction ratio of 6:1. An arm on the breaker-plate shaft actuates limit switches at both extremes of travel of the breaker plate. The servo unit is bolted to the under side of the magneto mounting pad.

One phase of the motor is energized directly from a 110-volt alternating-current line. The second phase is energized by the output of a standard commercial amplifier, which utilizes a vibrator to convert a direct-current input signal to alternating current before amplification. A selector switch determines which of two available signals (manual or automatic) is to be fed to the amplifier. Both input signals are of the order of 10 millivolts direct current. A fixed "bucking" voltage of the same order of magnitude, that is, 10 millivolts opposes the input signal. When the input signal equals the bucking voltage, the amplifier output is zero; therefore, the motor is at rest and the system is at balance.

Manual control of spark timing is achieved by varying the manually controlled battery voltage above or below the bucking-voltage level until the desired spark timing is reached.

Automatic control of spark timing is achieved by means of a thyatron trigger circuit. The circuit (fig. 6) consists essentially of a vacuum tube (6J5, triode) in series with a thyatron (934). The thyatron is shunted with a 50,000-ohm resistor, which completes the series circuit through the triode when the thyatron is extinguished. In normal operation the thyatron is biased below its firing point. During the time of passage of the flame front, the ionization gap in the combustion chamber breaks down and applies a positive firing voltage on the grid of the thyatron allowing the thyatron to conduct current. An engine-driven switch set to close momentarily at about 100° A.T.C. applies a negative impulse to the grid of the triode driving it to cut-off, which breaks the circuit and extinguishes the thyatron. The triode conducts current as soon as the biasing switch opens and the circuit returns to normal operation.

Successive firing and extinguishing of the thyatron produces a square-wave voltage of constant amplitude across a 10,000-ohm resistor in the cathode circuit of the thyatron. The length of time during which the thyatron conducts current depends upon the point at which it is fired by the ionization gap; therefore, the width of the positive portion of the cycle is a function of the position of the maximum rate of pressure rise. The direct current that results from filtering the direct-current square wave is the second of the two signals that may be fed into the amplifiers.

The input polarity and the direction of rotation of the motor are such that as the ionization gap tends to break down sooner, the spark is retarded until the point of maximum rate of pressure rise returns to its original position and the system is rebalanced. Conversely, as the gap tends to break down later, the spark is advanced until balance is restored.

Limit switches so open the plate circuit of the proper power output tube of the amplifier that motor travel in either direction is restricted but the motor can reverse and travel in the opposite direction. These limit switches also control warning lights on the instrument panel. The warning light, which shows that the spark timing is fully retarded, can be used to indicate preignition of the engine.

The functioning of the instrument as a preignition indicator is possible because when preignition occurs the crank angle of maximum rate of pressure rise  $\theta_r$  is advanced considerably and the spark timing no longer controls the time of combustion. The instrument for controlling the spark timing therefore acts to retard the spark and proceeds to the limit of its travel. The reaching of this limit is indicated by the warning signal (a light marked "preignition" on the instrument, fig. 5).

Spark timing is shown on the instrument panel by the position indicator, which is electrically driven by the position transmitter geared to the motor shaft.

Originally the thyatron was to be triggered by the output of a magnetostriction-type knock pickup, however, this method was not used because it necessitated use of an additional amplifier. If the knock pickup were used, the instrument would be directly controlled by the crank angle of maximum rate of pressure rise.
